Introduction to Mirrors and Lenses

Introduction to Mirrors

As we look around the room, we see most objects by the light that is diffusely reflected from them.

Diffuse reflection of light takes place when the surface of the object is not smooth. The reflected rays from a diffusely reflecting surface leave the surface in many different directions.

When the surface is smooth, such as the surface of glass or a mirror, then it can be easily demonstrated how reflected rays always obey the law of reflection as illustrated below.
Law of Reflection

The angle of incidence is equal to the angle of reflection.

\[ i = \text{Angle of Incidence} \quad r = \text{Angle of Reflection} \]

\[ r = i \]

(See Glossary, page 63.)

The Image Formed by Reflection in a Flat Mirror

Every object we see has many rays of light coming from it either by reflection or because it is a light source such as a light bulb, the Sun, a star, etc. Each point on that object is a source of light rays. In the illustration below, the tip of the arrow is used as an example of a point on the object from which rays of light would be coming. As the rays from the object are reflected by the mirror, the reflected rays appear to come from the image located behind the mirror at a distance equal to the object’s distance from the mirror. The image is called a virtual image since the rays do not actually pass through or come from the image; they just appear to come from the image as illustrated below.
The Image Formed by a Concave Mirror

A concave mirror that is part of a ball or hollow sphere (that is, it has a circular cross section) is a spherical mirror. The focal length is approximately one-half the radius of curvature. A ray that is both parallel and very close to the optical axis will be reflected by the mirror so that it will cross the optical axis at the “paraxial focal point.” The paraxial focal point is located a distance of one-half the radius of curvature from the point on the mirror where the optical axis intersects the mirror. The word “paraxial” comes from the Greek “para” or “par” meaning “at the side of, or beside, and axial.” Thus paraxial means beside the axis.

Another ray that is parallel to the optical axis, but not close to the axis, will be reflected by the mirror so that it crosses the optical axis, not at the paraxial focus, but a small distance closer to the mirror. This difference in the axis cross-over points is called spherical aberration.

If the mirror has a cross section that is a parabola instead of a circle, all of the rays that are parallel to the optical axis will cross at the same point. Thus, a paraboloidal mirror does not produce spherical aberration. This is why the astronomical telescope known as the Newtonian (invented by Isaac Newton) uses a paraboloidal primary mirror.

For demonstration purposes in the classroom, it works out that we can make the approximation that spherical mirrors behave almost like paraboloidal mirrors and determine that the focal length of a spherical mirror is about one-half the radius of curvature of the mirror.
In the case where the object is located between the focal point and the mirror, such that the object distance is less than the focal length of the mirror, a virtual, upright, and enlarged image is obtained. This is the case when looking at yourself in a concave “make-up” mirror, which is described below.

A ray (1) appearing to come from the focal point strikes the mirror and is reflected parallel to the optical axis. A ray (2) parallel to the optical axis is reflected by the mirror so that it goes through the focal point. A ray (3) striking the mirror at the optical axis is reflected so that the angle of reflection is equal to the angle of incidence.

The ray diagram below uses three reflected rays to illustrate how the image can appear to be enlarged and upright. The image formed is a virtual image.

The Image Formed by a Convex Mirror

The image formed by a convex mirror is virtual, upright, and smaller than the object. This is illustrated by the ray diagram on the following page. The diagram depicts the three rays that are discussed in the following paragraph.

A ray (1) parallel to the optical axis is reflected as if it came from the focal point (f). A ray (2) directed toward the focal point is reflected parallel to the optical axis. A ray (3) striking the mirror at the optical axis is reflected at an angle equal to the angle of incidence.
Introduction to Lenses

A simple lens is a piece of glass or plastic having two polished surfaces that each form part of a sphere or ball. One of the surfaces must be curved; the other surface may be curved or flat. An example of a simple lens would be obtained if a piece of a glass ball were sliced off as shown in the following illustration.

The piece of the ball sliced off would be a lens with a spherical side and a flat side. Lenses can be made in a variety of shapes for various applications. Some examples of lens shapes are illustrated here.
The Image Formed by a Converging Lens

When using a thin lens, that is, the thickness at the center of the lens is not too great, a thin lens mathematical approximation can be used. This approximation assumes the bending of light occurs in one plane inside the lens.

A ray of light coming from a very distant object, such that the ray is parallel to the optical axis, will be bent by refraction at the two surfaces of the lens and will cross the optical axis at the focal point (f) of the lens, as seen in the illustration below. A ray passing through the center of the lens will pass through the lens undeviated.

The size and location of an image formed by a lens can be found by using the information from these two rays which is shown in the illustration below.

The following illustration depicts two rays, which are defined in the following text. A ray (1) parallel to the optical axis passes through the focal point (f). A ray (2) passing through the center of the lens is undeviated.

The image is real, smaller than the object, and upside down. If a piece of paper is placed at the image location, a real image can be seen on the paper. An example of this is taking a picture with a camera, where the photographic film is located at the image position.
A Simple Magnifier

When the object lies between the lens and the focal point, a virtual, upright, and enlarged image is obtained, as seen in the illustration below.

Three rays are included in the illustration. Following are descriptions of these rays. A ray (1) leaving the object parallel to the optical axis will bend at the lens and go through the focal point \( f \). A ray (2) leaving the object going through the center of the lens will be undeviated. A ray (3) leaving the object as if it came from the front focal point of the lens will bend at the lens and travel in a line parallel to the optical axis.

After passing through the lens, the three rays described above will appear to come from an enlarged and upright image. Any other ray leaving the tip of the object will appear to come from the tip of the image after passing through the lens. The three rays used in the illustration below were chosen because their paths are always known. Two rays are actually enough to locate the image, while the third ray is used for an additional check of the location of the image.
